Chapter 1

Introduction

The amount of hateful content spread online on social media platforms remains a significant problem. Ignoring its presence can harm people and even result in actual violence and other conflicts (Balayn et al., 2021; Council of Europe, n.d.). There are many news articles about events where hate spread on online platforms lead to acts of violence (Ingram, 2018; Mashal et al., 2022; Mozur, 2018; Müller & Schwarz, 2021). One research paper found a connection between hateful content on Facebook containing anti-refugee sentiment and hate crimes against refugees by analyzing social media usage in multiple municipalities in Germany (Müller & Schwarz, 2021). Governmental institutions and social media companies are becoming more aware of these risks and are trying to combat hate speech. For example, the European Union developed a Code of Conduct on countering illegal hate speech in cooperation with large social media companies such as Facebook and Twitter (European Commission, 2016). This Code of Conduct requests companies to prohibit hate speech and report their progress every year (European Commission, 2016). The most recent report from 2021 stated that Twitter only removed 49.5% of all hateful content on their platform. Facebook is most successful in removing hate speech as they claim to have removed 70.2% of all hateful content in 2021 (European Commission, 2016). However, one article found in internal communication from Facebook that this percentage is much lower, around 3-5% (Giansiracusa, 2021). Therefore, hate speech detection remains a hard problem that even large institutions have not solved yet.

Currently, people rely on reactive and proactive content moderation methods to detect hate speech (Klonick, 2018). Reactive moderation is when social media users are flagging (also known as reporting) hateful content (Klonick, 2018). Proactive moderation is either done automatically using detection algorithms or manually by a group of human moderators (Klonick, 2018). There exist different methods for automatically detecting hateful content. Most use Machine Learning (ML) algorithms since these tend to be the most promising for their detection performance at a large scale (Balayn et al., 2021; Fortuna & Nunes, 2018). These algorithms can range from traditional ML methods such as Support Vector Machine or Decision Tree to Deep Learning algorithms (Fortuna & Nunes, 2018).

However, both proactive and reactive moderation methods have their limitations. Proactive manual moderation of hateful content is still the most reliable solution but is simply infeasible due to the large amount of content generated by the many users (Balayn et al., 2021). Reactive moderation solves this problem since the users can report hate speech themselves. Although, the problem stays that hateful content is exposed to the users for some time. Proactive automatic moderation using automated detection algorithms allow for large amounts of data to be checked quickly without the involvement of humans. However, these algorithms have shown to be unreliable as they often perform poor on deployment data (Balayn et al., 2021; Gröndahl et al., 2018). One study found that the F1 scores reduce significantly (69% F1 score drop in the worst case) when training a hate speech detection model on one dataset and evaluating it using another dataset (Gröndahl et al., 2018). Furthermore, one paper found that most research in hate speech detection overestimates the performance of the automated detection methods (Arango et al., 2019). The authors found that the performance drops significantly when the detection algorithms are trained on one dataset and evaluated on another (Arango et al., 2019).

This thesis research will tackle the problems of proactive moderation by focusing on the concept of *human-machine co-creation* (Woo, 2020) where the advantages of both humans (cognitive abilities and ability to make judgements) and machines (automation and performance) are combined. So humans and machines should work together to detect hate speech. ML models should detect hateful content automatically and humans should make the final decisions (*human-in-the-loop*) when the model is not confident enough (Woo, 2020). Here come ML models with a reject option in place. The goal of the reject option is to reject an ML prediction when the risk of making an incorrect prediction is too high and to defer the prediction task to a human (Hendrickx et al., 2021). There are several advantages. First, the utility of the ML model increases as only the most confident (and possibly the most correct) predictions are accepted. Second, less human effort is necessary as the machine is handling all prediction tasks, and only a fraction needs to be checked by a human. To the best of our knowledge, ML with rejection has not been used in hate speech detection before.

In this work, we focus on *value-senstive* rejection. There are gains of accepting correct predictions (positive value) and costs of accepting incorrect or rejecting predictions (negative value). We should weigh these values according to the task of hate speech detection and incorporate them in the design of the hybrid human-AI system (Sayin et al., 2021). We will mainly focus on the user-centred value since the social media users are the most affected by the consequences of hate speech.

The idea of most ML models with rejection is that we reject predictions when the model's confidence is too low. Therefore, we need a metric that measures the total value of ML models with a reject option. We can use the resulting metric to determine when to reject/accept predictions by maximizing the total value. Second, we need to find out how we can define the user-centred values in the context of hate speech detection. We will attempt to retrieve the value ratios since it is hard to come up with the absolute cost values in the hate speech domain. By value ratios, we mean to figure out, for example, the ratio between an FP and an FN prediction. Therefore, our first sub-research question is as follows:

This leads to the following research questions:

RQ How can we reject predictions of Machine Learning models in hate speech detection in a value-sensitive manner?

- **SRQ1** How can we measure the value of Machine Learning models with a reject option?
- **SRQ1** How can we determine the value ratios between rejections and True Positive (TP), True Negative (TN), False Positive (FP), and False Negative (FN) predictions?

Here comes a list of contributions

Here comes a short description of the structure of the thesis report

Chapter 2

Related work

In this chapter, we first define hate speech in section 2.1 and explain why it is such a challenging topic to tackle, especially from a computer science perspective. Then, we give an overview of the state-of-the-art solutions for the automatic detection of hate speech in section 2.2. In section 2.3, we discuss the different types of ML models with a reject option. Section 2.4 discusses the main challenges of assessing the values of (in)correct and rejected predictions in the hate speech domain. Finally, we discuss the shortcomings of standard machine metrics, such as accuracy, to evaluate detection systems and why human-centred metrics are promising.

2.1 Hate speech: definition and challenges

Different types of online conflictual languages exist, such as cyberbullying, offensive language, toxic language, or hate speech, and come with varying definitions from domains such as psychology, political science, or computer science (Balayn et al., 2021). We can broadly define *hate speech* as *"language that is used to express hatred towards a targeted group or is intended to be derogatory, to humiliate, or to insult the members of the group"* (Balayn et al., 2021; Davidson et al., 2017). It differs from other conflictual languages since it focuses on specific target groups or individuals (Balayn et al., 2021).

Balayn et al. (2021) identified the mismatch between the formalisation of hate speech and how people perceive it. Many factors influence how people perceive hate speech, such as the content itself and the characteristics of the target group and the observing individual, such as gender, cultural background, or age (Balayn et al., 2021). We can identify this mismatch in other related work from which there appears to be low agreement among humans regarding annotating hate speech (Fortuna & Nunes, 2018; Ross et al., 2017; Waseem, 2016). Ross et al. (2017) found low inter-rater reliability scores (Krippendorff's alpha values of around $0.2 - 0.3$) in a study where they asked humans about the hatefulness and offensiveness of a selection of tweets. They also found that the inter-rater reliability value does not increase when showing a definition of hate speech to the human annotators beforehand. Waseem (2016) found a slight increase in the inter-rater reliability when considering annotations of human experts only, but it remained low overall.

In the hate speech domain, we need to careful with creating biased detection systems using biased datasets. Most annotated hate speech datasets that are publicly available are likely to be biased. Datasets such as Waseem and Hovy (2016) or Basile et al. (2019) collected their data using specific keywords that can introduce *sample retrieval* bias and annotated their data using only three independent annotators that might result in *sample annotation* bias (Balayn et al., 2021). Automated classification models will likely become biased in their predictions if we train them on biased datasets (*garbage in, garbage out*). This phenomenon becomes most notable when applying pre-trained classification models to new and unseen data in deployment. For example, Gröndahl et al. (2018) and Arango et al. (2019) report significant drops in F1 scores when training a hate speech classification model on one dataset and evaluating it on another. Gröndahl et al. (2018) found that the F1 score reduces by 69% in the worst case and that the model choice does not affect the classification performance as much as the dataset choice. Arango et al. (2019) replicated several state-of-the-art hate speech classification models and found that most studies overestimate the classification performance. These results further strengthen our stance that we should not detect hate speech solely by machines but rather by a human-in-the-loop approach.

2.2 Automatic hate speech detection

In this section, we will list the state-of-the-art Natural Language Processing (NLP) techniques for automatic hate speech detection from literature. Several excellent surveys outlined the different detection methods from literature (Fortuna & Nunes, 2018; Schmidt & Wiegand, 2019). First, we will discuss the different features used in the classification models. Then, we will state the most used classification models ranging from supervised to unsupervised learning.

Commonly used features are bag-of-words (BOW) (Greevy & Smeaton, 2004), character/word N-grams (Waseem & Hovy, 2016), lexicon features (Xiang et al., 2012), term frequency-inverse document frequency (TF-IDF) (Badjatiya et al., 2017; Davidson et al., 2017; Rodriguez et al., 2019), part-of-speech (POS) (Greevy & Smeaton, 2004), sentiment analysis (Rodriguez et al., 2019), topic modelling (e.g. Latent Dirichlet Allocation (LDA)) (Xiang et al., 2012), meta-information (e.g. location) (Waseem & Hovy, 2016), or word embeddings (Agrawal & Awekar, 2018; Badjatiya et al., 2017). Greevy and Smeaton (2004) found that the classification performance is higher with BOW features than with POS features. Waseem and Hovy (2016) found that character N-gram achieves higher classification performance than word N-gram. They also found that using demographic information such as the location does not improve the results significantly. Xiang et al. (2012) used a lexicon feature (whether a social media post contains an offensive word or not) and the topic distributions from an LDA analysis. Rodriguez et al. (2019) used TF-IDF and sentiment analysis to detect and cluster topics on Facebook pages that are likely to promote hate speech. Badjatiya et al. (2017) experimented with different word embeddings: fastText[1], GloVe[2], and random word embeddings.

Most hate speech-related studies use supervised learning techniques that range from traditional ML to deep learning (DL) models, and a few use unsupervised learning techniques to cluster the social media posts. Support Vector Machine (SVM) (Davidson et al., 2017; Greevy & Smeaton, 2004; Xiang et al., 2012) and Logistic Regression (LR) (Davidson et al., 2017; Waseem & Hovy, 2016) are the most popular traditional ML techniques for hate speech detection. Davidson et al. (2017) found that SVM and LR perform significantly better than other traditional ML techniques such as Naive Bayes, Decision Trees, and Random Forests. Badjatiya et al. (2017) experimented with various configurations of word embeddings and two DL models: a convolutional neural network (CNN) and a long short-term memory (LSTM) model. They found that CNN performs better than LSTM and that using pre-trained word embeddings such as GloVe does not result in better classification performance than

[1] https://fasttext.cc/

[2] https://nlp.stanford.edu/projects/glove/

using random embeddings. Given the recent popularity of Bidirectional Encoder Representations from Transformers (BERT) models (Devlin et al., 2018) in the NLP field, studies such as (Alatawi et al., 2021) found that BERT models achieve slightly better classification performance than DL models. Rodriguez et al. (2019) use the unsupervised learning method, K-means clustering, to cluster social media posts for identifying topics that potentially promote hate speech.

2.3 Machine Learning models with rejection

Several studies promoted the concept of rejecting ML predictions when the risk of producing an incorrect prediction is too high so that a human gives the final judgement instead (Hendrickx et al., 2021; Sayin et al., 2021; Woo, 2020). Hendrickx et al. (2021) identified three ways for rejecting ML predictions: the *separated*, the *integrated*, and the *dependent* way. In the separated way, the rejectors decides beforehand whether a data sample needs to be handled by the classification model or by a human (Hendrickx et al., 2021). In the integrated way, the rejector is integrated in the classification model(Hendrickx et al., 2021). In the dependent way, the rejector analyzes the output of the classification model to determine whether to reject a prediction or not (Hendrickx et al., 2021). Several studies have applied the reject option using one of the architectures mentioned above (Coenen et al., 2020; De Stefano et al., 2000; Geifman & El-Yaniv, 2017, 2019; Grandvalet et al., 2008).

Coenen et al. (2020) developed a *separated* rejector that rejects data samples before passing them to the classification model. They used different outlier detection techniques, such as the one-class Support Vector Machine (SVM), to detect data samples that are unfamiliar with the training data (Coenen et al., 2020).

Dependent rejectors are the most commonly used (De Stefano et al., 2000; Geifman & El-Yaniv, 2017; Grandvalet et al., 2008). Grandvalet et al. (2008) experimented with support vector machines (SVMs) with a reject option. Geifman and El-Yaniv (2017) developed a dependent rejector that rejects data samples based on a predefined maximum risk value and the coverage accuracy of the classification model (Geifman & El-Yaniv, 2017). De Stefano et al. (2000) were among the first to develop a dependent rejector for neural networks. The authors developed a confidence metric for determining the optimal rejection threshold (De Stefano et al., 2000). This threshold is calculated based on a set of predictions with their corresponding confidence values and a set of cost values: the cost of incorrect, correct, and rejected predictions. (De Stefano et al., 2000).

Geifman and El-Yaniv (2019) developed an *integrated* rejector by extending their work from Geifman and El-Yaniv (2017). They integrated the reject option in a DL model by including a selection function in the last layer of the DL model.

In this work, we apply the dependent way since it supports any existing classification model (Hendrickx et al., 2021). The most relevant work is from De Stefano et al. (2000) since their confidence metric takes the value of (in)correct and rejected predictions) into account. While they experimented with a range of different cost values, we go further by employing a value-sensitive approach, which determines cost values based on how users feel regarding machine decisions using a survey study with crowd workers. Thus, we obtain a threshold that captures the implications of machine decisions from a human perspective.

2.4 Value assessment

We follow the suggestions from Sayin et al. (2021) and Casati et al. (2021) about incorporating *value* in the design of a hybrid human-AI system, in our case a hate speech classification model with a reject option. Another study from Fjeld et al. (2020) outlined 8 principles of AI systems where *fairness and discrimination* (e.g. algorithmic bias), *human control of technology* (e.g. the system should request help from the human user in difficult situations), and *promotion of human values* (we should integrate human value in the AI system) are the most important in our case. However, value is a broad term and its definition is context-dependent but several works elaborate on the value-sensitive design (VSD) approach that describes how different types of value, such as privacy, can be integrated in the design of a socio-technical system (Umbrello & Van de Poel, 2021; Zhu et al., 2018). We will mainly focus on the first step from the VSD approach about understanding the stakeholders so that we can assess their values (Umbrello & Van de Poel, 2021; Zhu et al., 2018). In this research, we focus on Machine Learning models with a reject option. We argued in the Introduction that this decision of rejection depends on the costs of incorrect predictions and the gains of correct predictions. We can express the costs of incorrect (FP and FN predictions) and rejected predictions as negative values. Therefore, we need to weigh the value of (in)correct and rejected predictions according to the task of case hate speech detection (Sayin et al., 2021). Accepting correct predictions

The gains of correct predictions (TP and TN predictions) as positive values. In some domains, we can define these values in money or time. For example, suppose there is a factory that uses a camera and an ML model to check if a package is damaged or not. Using an ML model will save the company time since these packages no longer have to be inspected manually by humans. However, the ML model could be incorrect sometimes. For example, a customer of the factory received a damaged package, while the ML model did not detect any damage. Fixing this issue could cost the factory money. At the same time, the factory could prevent these cases by rejecting the low confidence predictions from the ML model. For example, the ML model predicted with low confidence that a package did not contain any damage. An employee can then inspect it to prevent the customer from receiving a damaged one. Manually checking the rejected ones costs the factory a fraction of the time/money compared to the first situation. In this example, we can easily express the values of FP, FN, TP, TN, and rejections in time/money spent/saved.

However, it is not evident to express these values in the hate speech domain. Two stakeholders can be considered in the design of a smart rejector: the social media company and its users. We mainly focus on the users in this research since they will be affected the most by hate speech.

In this section, we will look at the related work to get an understanding of how we could retrieve the value ratios in hate speech detection. The goal is to retrieve ratios between rejection, FP, FN, TP, and TN cases. We would like to know whether an FN is, for example, two times worse compared to an FP. The main challenge is to express all values using a single unit. We could take two directions. First, we could define the values using an objective measure, such as time or money spent/saved. Second, we could define the values subjectively, e.g. by analyzing people's stance towards the consequence of incorrect predictions in hate speech detection. In the next two sections, we discuss the relevant related work in both directions.

2.4.1 Objective assessment

In this section, we explain the difficulties of defining the values using objective measurements. We do this by looking at some related work. We can retrieve the value of rejection by looking at how much time a human moderator spends on average to check whether some social media post contains hateful content or not. We can convert this into money by taking the moderator's salary into account. We could also argue that the value of a TP and a TN is equal to the negative value of rejection since we saved human effort by letting the classification model correctly predict whether something is hateful or not. The problem, however, starts to arise when we look at the FP and the FN predictions. How can we express the values of FP and FN predictions in terms of money or time?

First, we look at the social media company as a stakeholder. As we explained in the previous section, the values of rejection, TP, and TN can be determined. So the values of FP and FN are yet to be defined. However, most social media companies are not transparent in how they moderate hate speech (Klonick, 2018). So we do not have clear insights into the costs for these companies. There do exist country-specific fines. For example, Germany approved a plan where social media companies can be fined up to 50 million euros if they do not remove hate speech in time ("Social media firms faces huge hate speech fines in Germany", 2017). However, this is location-specific, and it is unclear how this applies to individual cases of hate speech. Defining the value of FP cases is even more difficult. It is unclear how filtering out too much content would affect the company (apart from many annoyed users whose freedom of speech is violated). Therefore, we abstain from estimating the values from the perspective of these companies.

Second, both FP and FN predictions have consequences on the users as the stakeholder. Having too many FP predictions might violate the value of Freedom of Speech since we are filtering out non-hateful posts and, therefore, we cause suppression of free speech. One paper found through a survey that most people think that some form of hate speech moderation is needed, but they also worry about the violation of freedom of speech (Olteanu et al., 2017). Having too many FN predictions might harm individuals or even result in acts of violence (Council of Europe, n.d.). Therefore, we need to figure out how we should weigh the values of FP and FN predictions accordingly. We abstain from using time as a unit since it does not make sense to express the consequences of hate speech or the benefits of freedom of speech in time. Therefore, we want to look at the value of freedom of speech and hate speech from an economic perspective. However, we noticed a lack of research in this area. There is one paper where they tried to come up with an economic model for free political speech by looking at the First Amendment to the United States Constitution (Posner, 1986). The First Amendment restricts the government from creating laws that could, for example, violate Freedom of Speech ("The Constitution", n.d.). The authors explained in Posner (1986) that the lack of research in this area is because most economists do not dive into the legal domain regarding free speech, and free speech legal specialists refrain from doing economic analysis (Posner, 1986). The proposed economic model from the paper, for example, includes the cost of harm and the probability that speech results in violence (Posner, 1986). However, the authors do not elaborate on how we can define the probability and the costs. Another paper did speculate on this topic by explaining why doing a cost-benefit analysis of free speech is almost impossible (Sunstein, 2019). The authors explained that there are too many uncertainties (Sunstein, 2019). We can assume that there are values of free speech, but it is too difficult to quantify them (Sunstein, 2019). For example, terrorist organizations use free speech to recruit people and call for acts of violence online (Sunstein, 2019). At the same time, most other hateful posts will not ever result in actual acts of violence (Sunstein, 2019). Therefore, cost values using objective measurements are often case-specific and cannot be defined generically. There is a nonquantifiable risk that acts of violence will happen in the unknown future (Sunstein, 2019). But suppose we do know this probability, then there are still too many uncertainties. To calculate the actual costs of hate speech (in our case: to accept the FN predictions), we also need to know the number of lives at risk and how we should quantify the value of each life (Sunstein, 2019)? The authors claim that analyzing the benefits of free speech is even more difficult (Sunstein, 2019). They conclude their work by saying that there are too many problems to empirically evaluate the costs and benefits in the hate speech context (Sunstein, 2019).

Therefore, we believe that using objective measurements, such as money, is not realistic for generically expressing the cost values in our project for both stakeholders.

2.4.2 Subjective assessment

- Focus on subjective values of users - Not companies

Initially, we considered using Likert scales as the response scales of our survey. However, as we will explain in the following subsection, Likert scales are not suitable for retrieving ratio values between the different scenarios of TP, TN, FP, FN, and rejections. Therefore, we will use a technique called Magnitude Estimation in our survey.

Likert

Likert scales are widely used in academic research for retrieving the opinions of a group of subjects. Likert scales are a series of multiple Likert-type questions where subjects can answer questions with several response alternatives **boone2012analyzing**. So in our case, we could use a bipolar scale with seven response alternatives ranging from 'strongly disagree' to 'strongly agree', including a 'neutral' midpoint. However, there is a lot of discussion in the literature about how we should analyze these Likert scales **boone2012analyzing; allen2007likert; norman2010likert; murray2013likert**. The scale of the questions is ordinal, which means that we do know the ranking of the responses, but we do not have an exact measurement of the distances between the response items **allen2007likert**. For example, we know that 'strongly agree' is higher in rank than 'agree', but not the exact distance between the two responses and whether it is greater than the distance between the 'neutral' and the 'somewhat agree' responses. Therefore, we technically cannot use parametric statistics, such as calculating the mean, when analyzing the data **allen2007likert**. Other papers argue that we can treat a Likert scale that consists of multiple Likert items as interval data and, therefore, applying parametric statistics will not affect the conclusions **boone2012analyzing; norman2010likert; murray2013likert**. So, we can calculate mean scores for TP, TN, FP, FN, and rejection scenarios and compare these with each other. For example, we can then verify that the mean value of FN cases is greater than the mean value of FP cases and conclude that the negative value of an FN is smaller than the negative value of an FP. Analyzing Likert scales from our surveys would at most provide us with interval data (data for which we know the order, and we can measure the distances, but there is no true zero point **allen2007likert**).

However, we need to have ratio data in this project since we want to know the exact value ratios of the TP, TN, FP, FN, and rejection scenarios.

Magnitude Estimation

In 2.4.2, we concluded that Likert scales are not suitable since they do not provide ratio data. In this research, we want to experiment with a technique called Magnitude Estimation (ME). The ME technique originates from psychophysicists where human subjects need to give a quantitative estimation of sensory magnitudes **stevens1956direct**. For example, in one experiment, human subjects are asked to assign any number that reflects their perception of the loudness of a range of sounds **stevens1956direct**. If the human subjects perceive the succeeding sound as twice as loud, they should assign a number to it that is twice as large. Researchers applied the ME technique to different types of physical stimuli (line length, brightness, duration, etc.) and proved that the results are reproducible and that the data has ratio properties **moskowitz1977magnitude**. Other works have shown that the ME technique is also useful for rating more abstract types of stimuli, such as judging the relevance of documents **maddalena2017crowdsourcing**, the linguistic acceptability of sentences **bard1996magnitude**, the strength of political opinions **lodge1979comparisons**; **lodge1976calibration**, and the usability of system interfaces **mcgee2004master**. Therefore, we think that ME is a promising method for judging the value ratios of hate speech detection scenarios.

The main advantage of ME is that it provides the ratio scale properties we need. Another advantage is that the scale is unbounded compared to other commonly used response scales, such as Likert scales. For example, suppose we first show a scenario and the subject provides a 'strongly disagree' judgment. Suppose we now present an even worse scenario. The subject is now limited to the response items in the Likert scale and can only give the same 'strongly disagree' judgement. We do not have this problem when using ME because the subject always has the freedom to assign a value of disagreement that is even larger. However, there are two main drawbacks of using ME. First, we need to normalize the results. Second, it can be hard to validate if we can use ME to measure the subjects' judgements for different scenarios of hate speech detection.

The resulting data needs to be normalized since each subject can use any value they like. For example, one may judge the scenarios using values of 1, 2, and 10, while another may use 100, 200, and 1000. Luckily, there are different solutions for normalizing ME data, such as modulus normalization **moskowitz1977magnitude**. The most commonly used method for modulus normalization is geometric averaging since this preserves the ratio information **moskowitz1977magnitude**; **mcgee2004master**. However, as opposed to the unipolar scales used in **bard1996magnitude**; **mcgee2004master**, we are using bipolar scales (disagree-agree). By including 0 (neutral) and negative values (disagree), we cannot use geometric averaging anymore because it uses log calculations **moskowitz1977magnitude**. Using the algorithmic mean is also not an option since it would destroy the ratio scale properties **moskowitz1977magnitude**. Therefore, we normalize the magnitude estimates by dividing all estimates of each subject by the maximum given value. This way, all magnitudes estimates are in the range [100, 100] while maintaining the ratio properties.

Most papers that use the ME method apply some form of validation. Cross-modality validation is a technique that is often applied to validate the ME results

bard1996magnitude. Psychophysicists compare the magnitude estimates to the physical stimuli **bard1996magnitude**. They analyze the correlation between the magnitude estimates and the physical stimuli by taking the log of each value and plotting them against each other **bard1996magnitude**. In the case of estimating line lengths, we can easily vary the line length, for example, by showing a line that is twice as long as the previous line. Subjects can then estimate the line length using a number twice as large. However, this becomes more difficult in the social science and psychology domains. In hate speech detection and other applications in social science and psychology, we do not have an exact measure of the stimulus **bard1996magnitude**. Luckily, related work has shown that ME is still a suitable technique for eliciting opinions about different types of non-physical stimuli **bard1996magnitude**; **mcgee2004master**; **maddalena2017crowdsourcing**; **lodge1979comparisons**. We can validate the magnitude estimates by adopting the cross-modality technique but instead compare judgements against judgements **bard1996magnitude**; **lodge1979comparisons**. Some papers analyze the correlation between different ME scales for validation, such as handgrip measurements or drawing lines **bard1996magnitude**; **lodge1976calibration**. Others compare ME with another validated scale that can be of any type. For example, in **maddalena2017crowdsourcing** about judging the relevance of documents, the authors compared the ME scale with two validated ordinal scales for the same dataset **maddalena2017crowdsourcing**. So, we also need to validate our findings by checking the correlation between the ME scale and another scale. Validating two different measures is a form of convergent validation **fitzner2007reliability**. Refer to **??** for more details about validation.

100-level scale

In 2.4.2, we concluded that we need to validate the ME scale by comparing it against another. We will use a bounded scale that consists of 100 numerical levels to validate the ME scale for four reasons. First, it is impractical in this project, given the limited budget, to use other ME scales, such as measuring the intensity of the subjects' handgrips to express their judgements. Second, there does not exist any suitable dataset that we can use for validation that contains human ratings of different scenarios in hate speech detection. Third, we concluded in 2.4.2 that Likert scales have limited response freedom. Finally, in **roitero2018fine**, the authors concluded that the 100-level scale provides more response freedom than course-grained Likert scales and has several advantages over ME in terms of usability and reliability. The 100-level scale is easier to understand than ME, does not require normalization, and provides more flexibility than Likert scales **roitero2018fine**. Therefore, we will create two separate surveys with the same scenarios where half of all subjects use the 100-level scale and the other half use the ME scale.

2.5 Evaluation metrics

Most hate speech-related studies evaluate their classification methods using standard *machine* metrics such as accuracy, precision, recall, or F1. Evaluation of classification models with a reject option is often done by analyzing the accuracy and the coverage of the classification model. Nadeem et al. (2009) proposed the use of accuracy-rejection curves to plot the trade-off between accuracy and coverage so that different classification models with a reject option can be compared. Casati et al. (2021), Olteanu et al. (2017), and Röttger et al. (2020) recognized the shortcomings of machine metrics such as accuracy and found a gap in the evaluation of hate speech detection systems. Röttger et al. (2020) found that it is hard to identify the weak points of classification models using machine metrics such as accuracy. Therefore, the authors presented a suite that consists of 29 carefully selected functional tests to help identify the model's weaknesses (Röttger et al., 2020). Each test checks different criteria, such as the ability to cope with spelling variations or detect neutral content containing slurs (Röttger et al., 2020). Our approach is different since we focus on measuring the performance of classification models with a reject option. Olteanu et al. (2017) promote using *human-centred* metrics that measure the human-perceived value of hate speech classification models. They found that the perceived value varies for fixed machine performance measurements, such as precision, and that it depends on the user characteristics and the type of classification errors (an offensive tweet labelled as hate (low impact) and a neutral tweet labelled as hate (high impact)) (Olteanu et al., 2017). Casati et al. (2021) propose developing new metrics for evaluating ML models with a reject option that considers domain-specific values. Our work aligns with both studies since we focus on creating a human-centred metric for evaluating hate speech detection systems with a reject option that incorporates value derived from a survey study.

Chapter 3

Value-sensitive rejection

3.1 Metric

Explain and proof our modified version of the metric from De Stefano

3.2 Hate speech detection models

3.2.1 Logistic Regression

3.2.2 CNN

3.2.3 DistilBERT

3.2.4 Calibration

Explain what model calibration is and why it's necessary

Chapter 4

Survey study

4.1 Research question and hypothesis

4.2 Method

4.2.1 Scales

4.2.2 Normalization

4.2.3 Design

Independent variables

Confounding variables

Control variables

Dependent variables

4.2.4 Planned sample

Participant Inclusion and Exclusion Criteria

Participant Compensation

Sample size

4.2.5 Materials

Survey tool

Data

4.3 Analysis

4.3.1 Validation

4.3.2 Reliability

Chapter 5

Results

5.1 Survey study

5.1.1 Value ratios

5.1.2 Reliability

5.1.3 Validity

5.2 Value-sensitive rejection

Chapter 6

Discussion

Answer research questions

Discuss future work

6.1 Survey study

6.2 Value-sensitive rejection

6.3 Implications

Explain that Olteanu et al., 2017 claims that we need more human-centred metrics instead of abstract metrics such as precision and we agree with that by introducing our own human-centred metric

6.4 Limitations

Hate speech is difficult domain as there tend to be a lot of disagreement between people about what is considered hate speech and what not. Ross et al. (2017) found low Krippendorff alpha values in a hate speech survey. So our findings are in line with theirs.

Explain limitations of the metric and the survey study

The rejection threshold is calculated using the test set. This test set needs to be as realistic as possible. Furthermore we need to have calibrated models since we rely purely on the confidence values. This is also hard to realize. Temperature scaling can help, but it is still limited.

6.5 Recommendations

Magnitude Estimation seems promising for future research.

Personal and demographic characterisitcs might have a big impact. So further analysis on those aspects seem relevant.

Chapter 7

Conclusion
